

Objective:

- Resolving issues related to pointer as data member.
- Focusing on Object's initialization and resource Allocation/de-allocation issues and issues related to object manipulation.
- And a bit of logic as always to keep your brains working ☺
 - Reduce Row Echelon Form

data → [2][0] dis

Challenge: Matrix ADT

Design an ADT 'Matrix' whose objects should be able to store a matrix of floating point values. Matrix ADT should also perform specified operations listed below related to matrices.

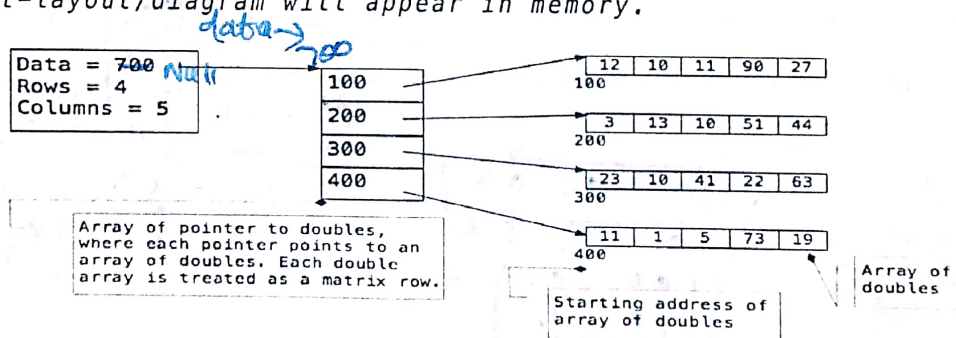

Data Members:

- double ** data; // pointer to an array of pointers whose each location //points to an array of floating point values
- int rows; // number of rows in matrix
- int columns; // number of columns in matrix

Supported Operations:

1. Matrix();
Set row and col to 0 and obviously initializes data to null as well. Represents a null matrix (0.25)

2. Matrix (int r, int c);
Set the r to rows and c to columns and creates matrix structure appropriately. If user sends invalid value in r or c or both then set them to 0. (1.0)
As an example, if we pass (4,5) to constructor, then following object-layout/diagram will appear in memory.

3. Matrix (const Matrix &)
The copy ctor; you know what to do. ☺ (2.0)

4. ~Matrix ();
Free the dynamically allocated memory. (1.0)

5. double & at(int r, int c);
For setting or getting some value at a particular location of matrix (0.25)

6. int getRows();
returns the number of rows of the matrix. (0.25)

7. int getColumns();
returns the number of columns of the matrix.

1 2 3
2 5 3
3 -3 9
[1, 2]
[2]

8. void display();
display matrix element on console.

1 2 3
2 5 3
3 -3 9

9. Matrix Transpose ();
Find Transpose of the *this object (calling object) and returns the transpose in a new Matrix object. No change in calling object. (1.0)

[1 2 3]
[4 5 6]
[7 8 9]

10. Matrix multiply (Matrix m2);
Multiply this(calling object) and m2 object and return the result in a new Matrix object. No change in calling object and received object. (3.0)

[1 4 7]
[2 5 8]
[3 6 9]

11. bool isEqual (Matrix m2);
returns true if the calling and received objects are equal otherwise false. No change in calling object and received object. (1.0)

[1 2 3]
[4 5 6]

12. void reSize (int newRow, int newCol);
resize the matrix according to new row and column. Make sure that the old matrix elements should be preserved in the new resized matrix if possible. (2.5)

[1 4 7]
[2 5 8]
[3 6 9]

13. bool isSymmetric ();
if $A^T = A$, then return true otherwise false. No change in calling object. (1.0)

14. void RREF ();
it converts the matrix into reduced row echelon form. (10.0)
//The First person who completes this in lab will get a reward.

Sample Run: for reduce row echelon form

```
int main()
{
    Matrix m(3,4);
    for (int i=0;i<m.getRows(); i++)
    {
        for (int j=0; j<m.getColumns(); j++)
        {
            cin>>m.at(i,j);
        }
    }
    m.RREF();
    cout<<"\n";
    return 0;
}
```

```

Program ended with exit code: 0

Some Examples: you may use for testing:

	Input Matrix				RREF			
1	2	1	-1	8	1	0	0	2
	-3	-1	2	-11	0	1	0	3
	-2	1	2	-3	0	0	1	-1
2	1	3	-1		1	0		-22
	0	1	7		0	1		7
3	1	2	1		1	0		1
	2	2	2		0	1		0
	1	0	1		0	0		0

Persistence and resilience only come from having been given the chance to work through difficult problems.

-- Gever Tulley --

The Gauss-Jordan algorithm

The input of the algorithm is an $m \times n$ matrix (not necessarily square!), which is typically an augmented matrix of a linear system, however the algorithm works for *any* matrix with numerical entries.

Start with $i = 1, j = 1$.

1. If $a_{ij} = 0$ swap the i -th row with some other row below to guarantee that $a_{ij} \neq 0$. The non-zero entry in the (i, j) -position is called a *pivot*. If all entries in the column are zero, increase j by 1.
2. Divide the i -th row by a_{ij} to make the pivot entry = 1.
3. Eliminate *all* other entries in the j -th column by subtracting suitable multiples of the i -th row from the other rows.
4. Increase i by 1 and j by 1 to choose the new pivot element. Return to Step 1.

The algorithm stops after we process the last row or the last column of the matrix.

The output of the Gauss-Jordan algorithm is the matrix in *reduced row-echelon form*.

Reduced row-echelon form

A matrix is in reduced row-echelon form (RREF) if it satisfies all of the following conditions.

1. If a row has nonzero entries, then the first non-zero entry is 1 called the leading 1 in this row.
2. If a column contains a leading one then all other entries in that column are zero.
3. If a row contains a leading one then each row above contains a leading one further to the left.

The last point implies that if a matrix in rref has any zero rows they must appear as the last rows of the matrix.
